

In the first half of the paper, we point out that there are two kinds of uncertainty in Probabilistic Image Registration (PIR), the transformation uncertainty and the uncertainty in the values of corresponding items (aka label uncertainty), e.g., intensity or tissue class. We give illustrated and real-data-validated example to share our finding that distinguishing these two quantities would result in a better characterization of the uncertainty of registration.

All reviewers seem to have a crucial misunderstanding as confusing "registration uncertainty" with "registration accuracy". We are aware that Rohlfing's paper, which R1 and R2 refer to, is an excellent work on the evaluation of registration accuracy. However, it's irrelevant with our research since we are not trying to study the relationship between uncertainty and accuracy.

R2 and R3 mischaracterize the paper as "proposing an intensity-based method...". This misunderstanding may partly due to our choice of terminology, albeit we clearly stated in section 2.1 that intensity is only an example of possible labels. In the final version, we will emphasize the term "label uncertainty" more often.

-Response to R1 R2-: They reject the paper mainly because they disagree with "our basic assumption" that is "low uncertainty in intensity is correlated with good registration". However, we never made that claim.

-Response to R2's example-: We respectively disagree. With different prior, the label uncertainty of a voxel on the boundary of a structure will not always be high. More over, it's questionable to consider registration uncertainty low at boundaries, especially for the boundary of tumor residuals in the neurosurgery context [Risholm MedIA13].

-Response to R3-: Comments from R3 indicate poor understanding of registration uncertainty.

In the second half of the paper, we draw attention to two important yet subtle aspects of PIR that reviewers seemed to ignore; we believe those findings are significant for the development, understanding, and usage of PIR.
