
Algorithm

Input:

\mathbf{I} = X-vectors of speech segments of one file

$[t_p^s, t_p^e]$ = time intervals of each period

\mathbf{P} = Number of periods in training

n_c^* = target number of clusters

Output:

\mathbf{y}^*, θ^* = final segment labels and model parameters

Steps:

1. $t=0, p=0$
 2. Initialize θ and initialize \mathbf{y} such that each segment belong to unique cluster
 3. **While** $p < P$; **do**
 4. Update \mathbf{y}^t to $\mathbf{y}^{t'}$ where $t' = t_p^e$ by merging two clusters at each time step
 5. if $t = t_p^e$ then
 6. Freeze \mathbf{y} and form triplets using it and compute loss.
 7. for E in epochs:
 8. Update θ^p to θ^{p+1} by training Neural Network
 9. $p = p+1$
 10. end if
 11. $t = t + t_p^s$
 12. Update \mathbf{y}^t to \mathbf{y}^* to get n_c^* clusters or selected clusters based on unsupervised calibration threshold
