

All functions take as input the four variables:

δ - the delay

α - the visibility

σ - the spectral width

ω_p - the pump frequency

The fixed shift probabilities take additional variables for the shifts. For mode-correlated noise, these are the two variables:

ϵ - the frequency-dependent shift

θ - the frequency-independent shift

For mode-uncorrelated noise, there are four shift variables:

ϵ_1 - the frequency-dependent shift for the c mode

ϵ_2 - the frequency-dependent shift for the d mode

θ_1 - the frequency-independent shift for the c mode

θ_2 - the frequency-independent shift for the d mode

The noisy probabilities and Fisher information instead take the additional variables:

$\eta\epsilon$ - the degree of frequency-dependent noise

$\eta\theta$ - the degree of frequency-independent noise

Variables are generally included in function even if the specific expression had no dependence on certain variables (such as HOM having no ω_p dependence, or the lack of visibility dependence in certain configurations)

P_1, P_2, P_c are the probabilities for detection at detector 1, detector 2, or a coincidence at both detectors respectively

F is the Fisher information

von Mises distribution

The noisy probabilities calculated in the paper and throughout this notebook assume Gaussian distributions for noise. For θ noise, this produces probabilities equivalent to the wrapped Gaussian distribution (see Appendix E).

An alternative circular distribution for θ noise is the von Mises distribution, this produces qualitatively the same behaviour but with slight differences in noise dependence.

A reader who wishes to obtain the noisy probabilities with a von Mises distribution may do so by taking the fixed shift probabilities in this notebook, and performing the integral in Eq. (25) replacing the θ distribution with

$$\ln[*]:= \text{J}\theta\text{VM}[\theta_ , \eta\theta_] := \frac{\text{Exp}\left[\frac{\cos[\theta]}{\eta\theta^2}\right]}{2\pi \text{BesselI}\left[\theta, \frac{1}{\eta\theta^2}\right]}$$

and integrating θ only between $-\pi$ and π .

(If ϵ noise is also being considered, its Gaussian distribution should remain and ϵ integrated between $-\infty$ and ∞)

Appendix E also includes comparison between Gaussian and von Mises distributions for θ noise for a few limited cases: MZ1, MZ2s, and MZ2d with frequency-entangled photons and mode-correlated noise.

As the noisy probabilities with von Mises have been calculated explicitly for these three cases, they are included below.

(Note all cases here assume no ϵ noise, so the $\eta\epsilon$ variable is absent from these expressions)

Adding Loss

This section allows for the generation of lossy probabilities for a given protocol configuration. Loss is represented by γ , the per photon loss rate.

First, run the earlier sections of this notebook to define all the non-lossy expressions.

Choose a protocol and configuration and run the cells for that choice. This will set the generic probability functions equal to the relevant probabilities for your chosen configuration.

Then, lossy expressions can be generated for either bucket detectors (i.e. those detectors that cannot distinguish between photon numbers) or number-resolving detectors.

Choose a detector type, and run the code for that section to generate probabilities and Fisher information.

Probabilities must be generated first before Fisher information, as the latter calls the probability functions.

The code will attempt to simplify the Fisher information expression. Sometimes this can take some time, the “TimeConstraint” parameter ensures simplification will cancel for cases where it takes too long (usually MZ2s cases). Increasing this parameter may allow more complicated simplifications to complete, though this may take some time to evaluate and there is no guarantee the automatic simplification will ever be possible for every configuration.
